9 Video Compression

9.1 Perception of motion

Perception of motion: Human visual system is specifically sensitive to motion. Eyes follow motion automatically. Some distortions are not as perceivable as in image coding (would be if we froze frame). No good psycho-visual model available. Vusal perception is limited to < 24Hz. Asuccension of images will be perceived as continuous if frequency is sufficiency high. Cinema 2424Hz, TV 25Hz or 50Hz. We still nee to avoid aliasing (wheel effect). High-rendering frame-rates desired in computer games (needed due to absence of motion blur). Flicker can be perceived up to > 60Hz in particular in periphery. Issue addressed by 100Hz TV.

9.2 Interlaced video format

Two temporarily shifted half images, increase of frequency 25Hz → 50Hz. Reduction of spatial resolution. Full image representation: progressive.

9.3 Why compress video?

Raw HD TV signal 720p@50Hz:
1280 · 720 · 50 · 24bits/s
= 1 105 920 000 bits/s > 1 Gb/s
Only 20Mb/s HDTV channel bandwidth requires compression of factor of 60 (0.4 bits/pixel on average)

9.4 Lossy video compression

Take advantage of redundancy. Spatial correlation between neighboring pixels. Temporal correlation between frames. Drop perceptual unimportant details.

Temporal Redundancy Take advantage of similarity between successive frames

Temporal processing

Usually high frame rate: Significant temporal redundancy. Possible representations along temporal dimension:

- 1 Transform/subband methods: Good for textbook case of constant velocity uniform global motion. Inefficient for nonuniform motion, i.e. real-world motion. Requires large number of frame stores which leads to delay. (Memory cost may also be an issue.) Is ineffective for many scene changes or high motion.
- 2 Prodictive methods: Good performance using only 2 frame stores. However, simple frame differencing is not enough...

Goal Exploit the temporal redundancy

Predict current frame based on previously coded frames

Types of coded frames:

- 1 I-frame: Intra-coded frame, coded independently of all other frames.
- 2 P-frame: Predictively coded frame, coded based on previously coded frame I or P. Can send motion vector plus changes.
- 3 B-frame: Bi-directionally predicted frame, coded based on both previous and future coded frames I and P. In case something is uncovered.

Motion-compensated prediction

Simple frame differencing *fails* when there is motion. Must account for motion. → Motion-compensated (MC) prediction. MC-prediction generally provides significant improvements. Questions: How can we estimate motion? How can we form MC-prediction?

Ideal situation

- 1 Partition video into moving objects
- 2 describe object motion → Generally very difficult

Practical approach Block-Matching Motion Estimation:

- 1 Partition each frame into blocks, e.g. 16 × 16 pixels
 - 2 Describe motion of each block
- No object identification required and good, robust performance.

9.5 Block-matching motion estimation

Assumptions:

- 1 Translational motion within block:
 $f(n_1, n_2, k_{cur}) = f(n_1 - mv_1, n_2 - mv_2, k_{ref})$.

ME Algorithm 1 Divide current frame into non-overlapping $N_1 \times N_2$ blocks.

- 2 For each block, find the best matching block in reference frame.

9.5.1 Determining the best matching block

For each block in the current frame, search for best matching block in the reference frame.

Metrics for determining “best match”:

MSE

$$= \sum_{n_1, n_2 \in \text{Block}} [f(n_1, n_2, k_{cur}) - f(n_1 - mv_1, n_2 - mv_2, k_{ref})]^2$$

MAE

$$= \sum_{n_1, n_2 \in \text{Block}} |f(n_1, n_2, k_{cur}) - f(n_1 - mv_1, n_2 - mv_2, k_{ref})|$$

Candidate blocks All blocks in, e.g. (±32, ±32) pixel area

Strategies for searching candidate blocks for best match.

- 1 Full search: Examine all candidate blocks
- 2 Partial (fast) search: Examine a carefully selected subset.

Motion vector Estimate of motion for best matching block.

9.6 Motion vector and motion vector field

Motion vector Expresses the *relative horizontal and vertical offsets* (mv_1, mv_2), or motion, of a given block from one frame to another.

Motion vector field Collection of motion vectors for all the blocks in a frame.

Example of fast motion estimation search

Motion Vector Precision

- Motivation: Motion is not limited to integer-pixel offsets. However, video is only known at discrete pixel locations. To estimate sub-pixel motion, frames must be spatially interpolated.
- Fractional MVs are used to represent

- sub-sub pixel motion.
- Improved performance (extra complexity is worthwhile)
- Half-pixel ME used in most standards: MPEG-1/2/4
- Why are half-pixel motion vectors better? They can capture half-pixel motion. Averaging effect (from spatial interpolation) reduces prediction error → Improved prediction. For noisy sequences, averaging effect reduces noise → Improved compression.

9.6.1 Practical Half-Pixel Motion Estimation Algorithm

Half-pixel ME (coarse-fine) algorithm:

- 1 Coarse step: Perform integer motion estimation on blocks; find best integer-pixel MV
- 2 Fine step: Refine estimate to find best half-pixel MV
- 3 Spatially interpolate the selected region in reference frame
- 4 Compare current block to interpolated reference frame block.
- 5 Choose the integer or half-pixel offset that provides best match Typically, bilinear interpolation is used for spatial interpolation

9.7 Block Matching Algorithm

Issues Block size, search range, motion vector accuracy

Estimate Done typically only from luminance

Advantages 1 Good, robust performance for compression.

- 2 Resulting motion vector field is easy to represent (one MV per block) and useful for compression.
- 3 Simple, periodic structure, easy VLSI implementations

Disadvantages

- 1 Assumes translational motion model → Breaks down for more complex motion.
- 2 Ofter produces blocking artifacts (OK for coding with Block DCT)

Bidirectional MC prediction is used to estimate a block in the current frame from a block in:

- 1 Previous frame
- 2 Future frame
- 3 Average of ablock from the previous frame and a block from the future frame
- 4 Neither, i.e. code current block without prediction

Example: Prediction with P- and B-frames

- 1 Motion compensated prediction: Predict the current frame based on reference frame(s) while compensating for the motion.
- 2 Examples of block-based motion-compensated prediction (P-frame) and bi-directional prediction (B-frame).

9.8 Frame types

Main addition over image compression: Exploit the temporal redundancy. Predict current frame based on previously coded frames. Three types of coded frames:

- 1 I-frame: Intra-coded frame, coded independently of all other frames
- 2 P-frame: Predictively coded frame, coded based on previously coded frame
- 3 B-frame: Bi-directionally predicted frame, coded based on both previous and future coded frames.

MPEG Group of Pictures (GOP)

Starts with an I-frame, ends with frame right before next I-frame. “Open” ends in B-frame, “closed” in P-frame. MPEG Encoding a parameter, but “typical”:

IBBPBBPBBBI,
IBBPBBPBBPBBBI.

Periodic I-frames enable random access into the coded bitstream. Parameters:

- 1 Spacing between I frames

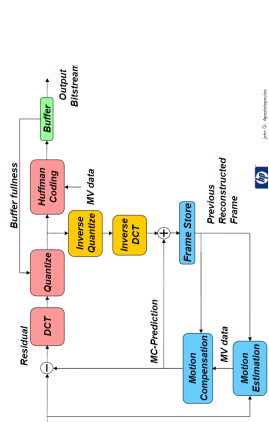

- 2 Number of B frames between I and P frames
- Example compression performance**
- I: $\frac{1}{7}$, P: $\frac{1}{20}$, B: $\frac{1}{50}$, Average: $\frac{1}{27}$.

9.9 Summary of Temporal Processing

- 1 Use MC-prediction (P and P frames) to reduce temporal redundancy.
- 2 MC-prediction usually performs well; In compression have a second change to recover when it performs badly.
- 3 MC-prediction yields
 - 4 Motion vectors
 - 5 MC-prediction error or residual → Code error with conventional image coder
 - 6 Sometimes MC-prediction may *perform badly*
 - 7 Examples: complex motion, new imagery (occlusions)
 - 8 Approach: 1. Identify frame or individual blocks where prediction fails
 - 2. Code without prediction

9.10 Basic Video Compression Architecture

- 1 Exploiting the redundancies:
 - 2 Temporal: MC-prediction (P and B frames)
 - 3 Spatial: Block DCT
 - 4 Color: color space conversion
- 2 Scalar quantization of DCT coefficients
- 3 Zigzag scanning, runlength and Huffman coding of the nonzero quantized DCT coefficients

Input Video Signal is split into RGB and YUV. RGB goes to a Buffer, then Huffman Coding, then Quantize, then Inverse Quantize, then Inverse DCT, then Frame Store, then Previous Reconstructed Frame. YUV goes to a Residual, then DCT, then MC-Prediction, then Motion Compensation, then Motion Estimation, then MV data, then Frame Store, then Previous Reconstructed Frame. The Residual is added to the Previous Reconstructed Frame to produce the Reconstructed Frame, which is then converted back to RGB and sent to the Buffer. The Buffer also receives input from the Input Video Signal.
